, so cm

in each of four configurations: as a single layer in contact with the skin; as a single layer with a 6.35 mm (one-fourth inch) air gap between fabric and skin; in conjunction with a cotton T-shirt with no air gaps; and, finally, in conjunction with a T-shirt with a 6.35 mm air gap between T-shirt and fabric. Bare skin was used as a control.

A JP-4 fueled furnace was used as a thermal source and was adjusted to deliver a mean heat flux of 3.07 cal/cm²/sec. The duration of exposure was five seconds. Four hundred burn sites were graded using clinical observation and microscopic techniques.

Used as single layers, none of the fabrics demonstrated superiority in providing clinically significant protection. When used with a cotton T-shirt protection was improved. Protection improved progressively for all fabrics and configurations when an air gap was introduced. The experimental high temperature polymer consistently demonstrated lower heat flux transmission in all configurations but did not significantly reduce clinical burns.

FOREWORD

The vivarium of the United States Army Aeromedical Research Laboratory (USAARL) is fully accredited by the American Association for the Accreditation of Laboratory Animal Care.

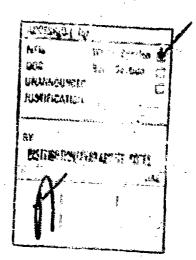

The animals used in this study were procured, maintained, and used in accordance with the Animal Welfare Act of 1970 and AR 70-18. In conducting the research described in this report, the investigators adhered to the "Guide for Laboratory Animal Facilities and Care," as promulgated by the Committee on the Guide for Laboratory Animal Resources, National Academy of Sciences, National Research Council.

All authors were research investigators at the USAARL during the conduct of the experiments described herein.

Dr. Knox is currently with the Department of Physiology and Biophysics, Louisiana State University Medical Center School of Medicine, Shreveport, Louisiana 71130.

Dr. Wachtel is currently with the Department of Surgery, University of California, San Diego, School of Medicine, San Diego, California 92103.

Dr. McCahan is currently with the Department of Toxicology and Criminal Investigation, State of Alabama, Enterprise, Alabama 36330,

SUMMARY

The United States Army Aeromedical Research Laboratory (USAARL) porcine cutaneous bioassay technique was used to determine what mitigating effect feur thermally protective flight suit fabrics would have on fire-induced skin damage. The fabrics were 4.8 oz twill weave Nomex aramide, 4.5 oz stabilized twill weave polybenzimidazole, a 4.8 oz plain weave experimental high temperature polymer, and 4.8 oz plain weave Nomex aramide. Each fabric sample was assayed 20 times in each of four configurations: as a single layer in contact with the skin; as a single layer with a 6.35 mm (one-fourth inch) air gap between fabric and skin; in conjunction with a cotton T-shirt with no air gaps; and, finally, in conjunction with a T-shirt with a 6.35 mm air gap between T-shirt and fabric. Bare skin was used as a control.

A JP-4 fueled furnace was used as a thermal source and was adjusted to deliver a mean heat flux of 3.07 cal/cm²/sec. The duration of exposure was five seconds. Four hundred burn sites were graded using clinical observation and microscopic techniques.

Used as single layers, none of the fabrics demonstrated superiority in providing clinically significant protection. When used with a cotton T-shirt protection was improved. Protection improved progressively for all fabrics and configurations when an air gap was introduced. The experimental high temperature polymer consistently demonstrated lower heat flux transmission in all configurations but did not significantly reduce clinical burns.

INTRODUCTION

A free field or helicopter postcrash JP-4 fuel fire reaches maximum intensity and "steady state" thermal dynamics 20 seconds after single point ignition. An aviator wearing a standard summer weight cotton flight uniform who is in the middle of such a conflagration must get out of the fireball within 10 seconds after ignition if he is to have a reasonable chance of survival. After 20 seconds, the aviator would be in a thermal environment with temperatures ranging from 927° C to 1260° C. Heat flux in controlled postcrash fires ranges from 2.79 to 7.45 cal/cm²/sec*.

Extensive studies conducted by the U.S. Army Aeromedical Research Laboratory (USAARL) and others^{1 2 4 7} have shown that postcrash fires are extremely variable in their time-course and in severity. These studies led to a definition of the worst credible thermal environment as 1149° C or 5.5 cal/cm²/sec.¹

During a postcrash fire, the aviator's clothing is the only barrier between the excessive thermal environment and the skin. The design of operational flight clothing requires consideration of fabric flammability, heat transfer characteristics, comfort, launderability, abrasion resistance, fabric strength and durability, color fastness and predicted useful service life, to mention only a few important factors. Since all design parameters cannot be optimized using present technology, each garment is always a compromise product. An aviator's flight suit may never be subjected to the hazardous thermal environment against which it was designed, but this design parameter must remain among the foremest in a selection process among several candidate fabrics or designs. Obviously any selection process is complex and requires consideration of cost, logistics, and user acceptance as important considerations.

From a thermal protective standpoint any selection of fabric or garment design must be based on an appropriate set of test procedures. These methods must recreate the posternal thermal environment in the laboratory and must quantitatively predict burns from measured thermal transfer through the fabric. For testing fabric samples, the ideal method would be to use physical thermal sensors such as calorimeters or skin simulants to measure the thermal transfer so one could predict from such data the burns that would

^{*}These heat flux calculations assume black body conditions calculated from Stefan-Boltzmann Law.

result. To do this with any degree of accuracy requires a mathematical model. However, mathematical models which generate burn predictions from measured thermal transfer are not, at this time, sufficiently accurate. Therefore, the use of a bioassay technique in which porcine skin is used as a model for human skin is recommended. The direct bioassay technique provides burn data that are readily understandable and acceptable to physiologists and clinicians. The data require no extrapolation for the fabric engineer.

The experiments described in this report show what mitigating effects four selected thermal protective fabrics have on skin damage thermally induced by exposure to a simulated posterash fire.

METHODS AND MATERIALS

Twenty white, cross-bred, male and female domestic swine (Sus scrofa domesticus) were procured locally, quarantined for at least 30 days, treated for any internal or external parasites, and verified to be healthy prior to use in this experiment. The animals were housed in a covered outdoor vivarium and weighed 43.9 ± 6.6 kg at the time of the experiment. The pigs were assigned randomly to one of four exposure groups of five animals each.

The swine were fasted overnight, premedicated with atropine (0.04 mg/kg) and fentanyl-droperidol (0.1 ml/kg), intubated and anesthetized with Halothane USP. Hair was removed from the test site by close clipping with a #40 clipper head. The anesthetized pigs were placed on a rolling animal carriage with an electrically activated pneumatically operated water-cooled shutter system (Figure 1, page 4). Each of the five pigs in a group received four separate exposures, two on each side, of five seconds duration to a standardized thermal source.

The thermal source was a JP-4 fueled furnace which delivered 3.07 ± 0.16 cal/cm²/sec (70-90% of this energy was radiative) (Figure 1, page 4). Furnace wall temperature and heat flux were continually recorded on FM magnetic tape for later off-line computer processing. Heat flux and exposure time were found to be uniform from one position to another. Each exposure area was divided into six circular burn sites by a multi-layer asbestos/wood template (Figure 2, page 4). The holes were either 4.0 cm or 5.9 cm in diameter. Template position five always contained a slug calorimeter to monitor the fire (Figure 3A, page 5). Sites one through four and six were either covered with fabric or left uncovered as a control (Figure 3B, page 5). Four fabrics were evaluated. They were 4.8 ox twill weave Nomex aramide,

4.5 oz stabilized twill weave polybenzimidazole, a 4.8 oz plain weave experimental high temperature polymer, and 4.8 oz plain weave Nomex® aramide (Figure 4, page 5). In the double layer configurations, the second layer always 100% cotton T-shirt (T). The textile characteristics for these factors are summarized in Table 1 (page 6).

From Table 2 (page 7) it is possible to determine which fabric a vered a particular burn site for each pig. For example, in treatment Group III, the left rear area on pig number three had new weave Nomex (NWN) in contact with the skin at burn site one and polybenzimidazole (PBI) in contact with 100% cotton T-shirt in contact with the skin at position four. This system of fabric layout insured the each fabric appeared in each test position four times and was tested a total of 20 times using each of the four methods of application. Thus, a five position by five fabric Latin square was replicated four times for each group.

Damage was documented photographically immediately after the exposure and 24 hours later. A clinical grade¹¹ was assigned immediately after exposure and again 24 hours later (Table 3, page 8).

A biopsy wa. ken from each site 24 hours after the exposure. This specimen included the area representing the highest clinical grade as well as contiguous normal tissue for comparison. Hematoxylin and eosin stained sections were graded according to criteria developed by Lyon, et al, 12 and Knox and Wachtel (Table 4, page 9). In addition to this grade, actual burn depth was measured optically, together with measurements of the normal epidermal and dermal thicknesses. These data were analyzed using analysis of variance and covariance. Fabric effects were tested for significance by the modified Newman-Kouls' tests.

RESULTS

From 20 pigs and 400 available burn sites, 371 clinical and 346 microscopic burn grades and 233 burn depths provided acceptable data. Grades and depths were assigned to their respective exposure groups by fabric and fabric configuration, i.e., single or double layer, in contact or spaced away. The mean and standard deviations were calculated for each group. These results are tabulated in Table 5 (page 11) and presented graphically in Figures 5, 6 and 7 (pages 11 and 12). The most severe burns (the ones with the highest grades) were associated with the unprotected control sites while least severe burn grades were found in groups using double layered fabric with the outer fabric spaced 6.35 mm away from the T-shirt inner layer.

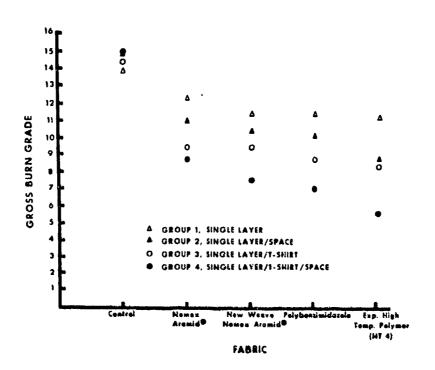

FIGURE 5. Mean Clinical (Gross) Grade for Each Fabric/Configuration.

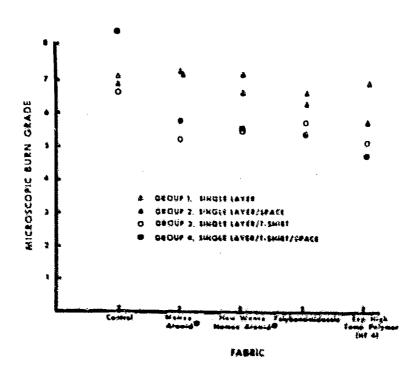

FIGURE 6. Mean Histopathological Microscopic Grade for Each Pabric/Configuration .

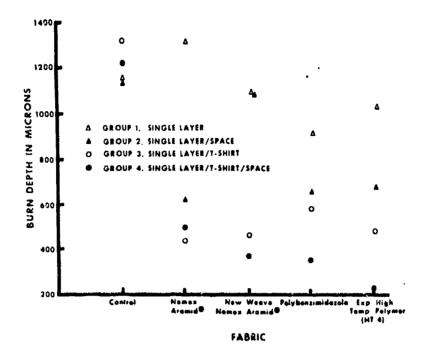

FIGURE 7. Mean Depth of Burn in Microns for Each Fabric/Configuration.

An analysis of variance and an analysis of covariance were performed using the control burn grades as a function of position with heat flux as the covariate to test the validity of the assumption of uniform flux. Table 6 (page 13) summarizes the results of this analysis of variance. Position and heat flux were not significant variables; therefore, they were eliminated as variables from the subsequent analysis.

An analysis of variance (Table 7, page 14) showed that the controls by Group were significantly different (p <0.01) for both microgrades and gross grades. The burn depths were not significant.

Examination of the data obtained from the sites which were completely unprotected from the fire showed some variation in the histopathological and in the gross evaluation scores, although there was no significant variation in measured burn depth (Table 7, page 14). The experimental design permits comparison of the effect of each fabric and each fabric configuration with all other fabrics and configurations tested. It is much more sensitive and specific to compare each with each other directly by the methods of analysis of variance. This was done, and the results of a modified Newman-Keuls' multirange test are summarized in Table 8 (page 15). In this test, means were arranged in ascending order, and lines were drawn beneath those treatment means which were not significant at p <0.05. Means not overlapped by the same line were significantly different at p <0.05.

DISCUSSION

Moritz and Henriques ¹³ have described porcine skin before and after thermal exposures and compared it to human skin burns, showing the relative vulnerability of porcine and human skin to thermal injury. They found little or no quantitative difference in the susceptibility of human and porcine epidermis to thermal injury at similar surface temperatures. Moritz¹⁴ delineated the pathogenesis and pathological characteristics of cutaneous burns in relation to the duration and intensity of thermal exposure and to the susceptibility to organization, repair, and healing.

Perkins, Pearse, and Kingsley¹⁵ demonstrated comparative surface appearance for similar threshold values (cal/cm²) for human and porcine skin subjected to radiant energy in epidermal and intradermal (and perhaps subdermal) burn lesions. Their data were comparable to the values of 2 cal/cm² for epidermal burns and 3.5 cal/cm² for deep intradermal burns in humans reported by Butterfield and Dixey¹⁶ and correlated well with the 3.9 cal/cm²/sec (0.54 sec exposure) value for subdermal human burns reported by Moncrief.¹⁷

The heat capacities and thermal conductivities of cutaneous and subcutaneous tissues of the pig, in vivo observations of caloric uptake of pigskin, rise in temperature at the dermis-fat interface as a function of both time and skin surface temperature, and an estimation of the temperature changes at the epidermal-dermal interface during the exposure of the skin surface to heat have been reported. Moritz, et al, have investigated the mechanisms by which thermal exposures, in which heat was transferred to the body through an envelope of air, cause disability and death.

Comparative studies of the skin of the domestic pig and human have been reported by Montagna and Yun.²⁹ They noted that the skin of the pig shares anatomical and histochemical features with that of man, although some dissimilarities exist.

Pigskin, like most animal models, is not perfect, but the weight of evidence on similarity of structure, comparability of burn damage, reaction of pigs as models for human burn shock²¹ and consistency of data obtained in testing lightweight underwear* argue in favor of using pigskin as the animal model of choice in a bioassay method for determining the thermal protective capability of fabrics.

į

An extensive review of the methods for simulating postcrash fire led to a proposal to use a new field fire simulation cell for testing whole flight garments. However, this device is not practical for testing candidate fabrics using the bioassay method. The flame gun used in an earlier study suffered from an imbalance in radiative and convective heating compared to naturally occurring postcrash fires. A method was needed which would more accurately duplicate the highly radiative nature (70 to 90%) of postcrash fires. Moreover, the chemical environment within the fire may be important in some circumstances in contributing to fabric failure; so, for this study, JP-4 fuel was used since it is standard for Army helicopters.

A survey of the available thermal sources such as Meeker burners, quartz lamps, carbon are lamps, and small pool fires led to the choice of a NASA designed furnace which does burn JP-4 fuel. When the furnace is at steady-state, the hot furnace wall simulates the radiation background of a field fire while the rich burning JP-4 fuel adds the convective and chemical environments.²

The five-second exposure time was chosen based on the results of a pilot experiment using one-, three-, five-, and seven-second exposures. The objective was to choose an exposure time which would result in deep dermal control burns.

The four methods of applying the fabrics to the skin were selected to simulate the ways in which various segments of a flight suit relate to a pilot's skin. This, of course, does not explore all the possibilities since, for example, double layers of outer shell fabric, zippers, and the like were not included.

As expected, fabries attenuated the thermal damage by varying amounts depending on the fabrie type and method of application. Double layers, especially those with air space between the layers, showed the greatest degree of protection. This confirms earlier data of Stoll, Stanton, Knox, Berkley, 33 and Mixter. 34

Of the various fabric types. Fabric HT4 gave more protection in each method of application than did any other fabric. However, it was only statistically significantly different from all others in the double-layered, spaced-away configuration (Group IV, HT4/T/S).

What, then, may be concluded from these observations? Under the conditions of this study there appears to be no clear choice among the fabrics

evaluated. HT4, while slightly better in attenuating heat flux, does not provide a significant increase in clinically significant protection. For example, consider the burn depths in Table 5 (page 10). Within each group the data are clustered, and the only clear improvement in protection comes as a result of adding double layers and air gaps. To be clinically significant a new fabric or uniform design must clearly lower morbidity. If, however, all the candidate fabrics fail to prevent burns in a given test, it raises several questions. First, was the test unreasonably severe? This would not appear to be the case, since the experimental conditions fit quantitatively within the known physical properties of actual postcrash fires. Second, were the methods of application reasonable? Here again the methods were chosen to simulate actual operational flight clothing use. Finally, is there such a thing as an acceptable burn? The ideal is clearly no burn at all. However, given the trade-offs which must be made in designing an acceptable flight suit, the ideal could probably only be achieved by entirely preventing the postcrash fire.

Given the reality of the occurrence of postcrash fires and the state of the art in flight clothing design, there will be burns. Decisions on new fabrics must take into account the available clinical data which relate age, sex, degree and area of burn, and survivability. For instance, an improvement of several hundred microns in burn depth would result in a corresponding increase in survivability. It is an increase in survivability which must be weighed against the cost and acceptability of a new flight garment. To predict survivability, however, one also needs to know the area burned in addition to the degree. This information is most readily obtained with properly designed and appropriately instrumented manikins subjected to full scale fires.

The study reported here emphasizes the general effectiveness of multiple layers and suggests that improvement can be achieved by redesign of present uniforms using multiple layers and present stocks of Nomex[®] and/or new weave Nomex[®] rather than going to new fiber types. This course is particularly prudent in the rotary-wing environment where installation of crashworthy fuel cells and newer crashworthy designs have resulted in reducing the threat of fire or fire induced injury.²⁵

Finally, it is difficult to evaluate fabric performance fully with a one point test in which only one heat flux and one exposure duration are used. Thermal protection and ultimate failure are a complex, dynamic process, and until understanding of that process improves, a one point test (especially, if pass/fail) is inadequate.

CONCLUSIONS

All fabrics evaluated provided some protection.

Multiple layers and fabric spacing are important factors in increasing the level of protection.

Fabric HT4 consistently gave the best protection, but this increased protection was not of clinical significance.
